Abstract – Six inclined poplar I-69 (*Populus deltoids* cv. I-69/55) trees were collected for studying the influence of growth stress level on wood properties. Growth stress indicator (GSI) was measured at eight positions around the periphery of each trunk at breast height and corresponding wood samples were obtained. Wood anatomical, physico-mechanical and chemical characteristics were measured, including cell diameter, fibre length, double wall thickness excluding the gelatinous layer, lumen diameter after gelatinous layer removal, proportion of wood tissues, basic density, FSP, MOE, compressive strength, shrinkage and chemical composition. Each property was regarded and discussed in relation to the growth stress level.

Résumé – Relation entre contrainte de croissance et propriétés du bois de peuplier I-69 (*Populus deltoides Bartr*. cv. "Lux" ex I-69/55). Six peupliers I-69 (*Populus deltoides* Bartr. cv. "Lux" ex I-69/55) inclinés ont été collectés pour étudier l'influence du niveau de contrainte de croissance sur les propriétés du bois. Des mesures d'indicateur de contrainte de croissance (ICC) ont été réalisées en huit positions à la périphérie de chaque tronc à 1,30 m et des échantillons ont été prélevés dans le bois à proximité. Des mesures anatomiques, physico-mécaniques et chimiques ont été réalisées : diamètre et longueur de fibre, épaisseur de la double paroi et diamètre du lumen hors couche gélatineuse, proportion des différents types de tissus, infradensité, point de saturation des fibres, module d'élasticité, limite élastique en compression, retrait et composition chimique. L'évolution des propriétés avec le niveau de contrainte de croissance est décrite et discutée.

1. INTRODUCTION

Trees control the shape and orientation of the main trunk or the predetermined angle of a branch, and search for light or react to stronger loading, such as a strong dominant wind, through the generation of growth stresses during the process of wood formation. This is usually obtained by production of so-called reaction wood. While gymnosperms produce compression wood in the lower face of stems, angiosperms produce tension wood generating high tensile stresses on their upper face [23, 55].

We will focus here on poplar tension wood, exhibiting important changes in the cell wall structure compared with normal wood [42]. In many species such as beech, poplar, oak or chestnut, tension wood contains fibres with a special morphology and chemical composition due to the development of the so-called gelatinous layer (G-layer) [42] replacing the S$_3$ layer and a part or the whole of the S$_2$ layer [48]. The G-layer is known to have high cellulose content with a high degree of crystallinity [15, 39] and to contain microfibrils oriented along the axis of the cell [25].

The distinctive anatomical characteristics and chemical composition of tension wood directly cause the changes in physical and mechanical properties which lead to technological problems, such as distortion of solid wood during sawing due to the release of high longitudinal growth stresses [7, 35, 40, 59], defects during drying due to its high longitudinal shrinkage [4, 19, 28, 42] and severe woolly surface during sawing and rotary cutting [43] due to G-fibres, as well as bad quality of paper made of G-fibres [44].

Poplar, an important fast-growing plantation tree for plywood, solid wood and paper manufacture, is well known to be very sensitive to the stimuli responsible for tension wood formation [27]. Studies at the microscopic level evidenced gradual changes in anatomical features from normal wood to severe tension wood, with corresponding variations in macroscopic behaviour [20, 21]. The aim of this work was to study the gradual changes in poplar I-69 (*Populus deltoids* cv. I-69/55) properties resulting from tension wood severity, as quantified by growth strain assessment.

2. MATERIALS AND METHODS

Six poplar trees (*Populus deltoids* cv. I-69/55) were collected in 2004 in the Islet beach of the Yangtze River in Anqing city, Anhui

Table I. Information on the six studied trees. DBH means diameter at breast height.

Tree	PC1	PC2	PC3	PC4	PC5	PC6
Lean angle from vertical position (°)	15.1	17.0	12.2	12.7	18.2	17.2
Height (m)	23.5	23.5	23.6	23.6	23.5	23.5
DBH in lean direction (cm)	29.0	32.0	31.0	28.0	25.5	29.0
DBH in lateral direction (cm)	27.0	30.0	28.0	25.0	25.0	28.5
DBH, average (cm)	28.0	31.0	29.5	26.5	25.3	28.8

province, China. The trees were planted in 1986. Their characteristics are given in Table I. Anatomical and chemical data were obtained in China, physical and mechanical data in France.

2.1. Growth Stress Indicator (GSI)

The "single hole" drilling method developed by the CIRAD [24] was used to estimate the longitudinal growth stress close to the trunk surface on the standing tree. The value in μm, termed growth stress indicator (GSI), relates to the longitudinal growth stress at the trunk periphery by a proportional factor depending on the mechanical anisotropy of the species. Hence, the GSI value is a good indicator of relative longitudinal growth stress magnitude within trees of the same species [12].

GSI measurements were performed on the 6 standing trees at 8 points around the circumference of the trunks at breast height. The points on the top upper sides of leaning trunks were noted as position 1 and then the other 7 points were positioned every 45° on the circumference and numbered in order from 2 to 8, so the lowest side was 5 (Fig. 1).

After GSI measurements, the trees were felled and eight directions corresponding to GSI measurement positions were marked on the trunk surfaces for the further studies. Moreover, a transverse section corresponding to each position was prepared for visual assessment of G-fibre occurrence by microscopic observation.

2.2. Anatomical properties

For each tree, close to positions No. 1 (upper side), Nos. 3 and 7 (lateral side) and No. 5 (lower side), two samples each were taken (Fig. 1). One was used for preparing a transverse section, the other for measurements of isolated elements after maceration. Transverse sections (20-μm thick) were obtained with a microtome with disposable blades, and double-stained with safranine and Fast Green. Safranine stains all tissues and Fast Green replaces safranine where purely cellulosic G layers of tension wood are present. This double-staining technique is used to detect and confirm tension wood occurrence (Fig. 2).

Sections were observed with an optical microscope linked to an image analysis system equipped with a colour CCTV camera (WV-CP460/CH, Panasonic). The sectioning method used caused the detachment and swelling of the G-layer [11, 14, 21], rending impossible any correct measurement of the real G-layer thickness and the real lumen diameter of G-fibres. Therefore, in this study only the double cell wall thickness excluding the G-layer, the lumen diameter after G-layer removal and cell diameter were measured. Thirty measurements per sample were made. The proportion of vessels and rays was measured by image analysis, allowing the calculation of the fibre proportion.

The other sample was macerated with mixed solution of half 10% nitric acid and half 10% chromic acid. After maceration, the measurement of fibre length was undertaken with a projection microscope.

2.3. Physical and mechanical properties

2.3.1. Basic density, fibre saturation point (FSP) and shrinkage

Samples, 20 mm in radial (R), 20 mm in tangential (T) and 50 mm in longitudinal (L) directions, were cut in the vicinity of GSI measurement positions (Fig. 1). Sample lengths in R, T and L directions were measured with a digital micrometer accurate to 0.001 mm. Following initial green weight and dimensions measurements, all samples were placed in three successive conditioning chambers set to provide nominal equilibrium moisture content (EMC) of 17% (30 °C, 80% RH), 12% (20 °C, 65% RH) and 8% (20 °C, 30% RH), respectively, then in an oven at 103 °C to obtain an EMC of 0%. At each stage, after constant weight was reached, samples were weighed and measured. Basic density (BD, g/cm^3) was calculated as the ratio between the ovendry weight and the saturated volume. FSP was obtained by calculating the intercept of shrinkage variation with moisture content change. Total T, R and L shrinkage, from saturated to ovendry, will be analysed in this study.

2.3.2. MOE, specific MOE and compressive strength

Samples (20 mm in R, 20 mm in T and 300 mm in L directions) were taken in the vicinity of GSI measurement positions (Fig. 1). Samples were kept in a controlled chamber with a temperature of 20 °C and humidity of 65% until the moisture content reached 12%. MOE and specific MOE were measured using free vibration and Fast Fourier Transform analysis (FFT). After dimensions and weight measurement, the wood sample was placed on two rubbers under a microphone that registers the noise accompanying the bending vibrations resulting from a small tap on one end with a little iron stick. The values were interpreted according to the Bordonné method [6], yielding the modulus of elasticity (MOE) and density, as well as specific MOE, defined as MOE / density. As the samples were long, it was difficult to avoid some defects such as knots, cracks and bends: finally, only 21 samples were used for MOE measurement.

The test of compressive strength parallel to grain was carried out following standard NF B 51-007 [1] (conforming to the international standard ISO 3787). Samples 20 mm (R), 20 mm (T) and 60 mm (L) were extracted from the samples used for MOE measurements (Fig. 1). Before measuring the compressive strength, the precise sample dimensions were measured. After the test the EMC of the sample during the test was measured. Compressive strength parallel to grain at 12% EMC σ_{12} (in MPa) was estimated using a correction valid for an EMC ranging between 7% and 18% [1]:

$$\sigma_w = \frac{P_{\max}}{a \times b} \tag{1}$$

$$\sigma_{12} = \sigma_w \times [1 + 0.04 \times (EMC - 12)] \tag{2}$$

where σ_w (MPa) is the compressive strength at the EMC of the test, $P_{\max}$ (N) the maximum force applied, and a and b the sample dimensions in R and T directions, respectively. This correction was required as the experiment was performed outside the conditioning room.
**Figure 1.** Schematic localisation of measurement positions.

Figure 2. Cross-sections of normal (left) and tension wood (right) where the G-layers appear green and other layers appear red after double-staining. Scale bar = 50 μm.

2.4. Chemical composition

The disc used for chemical composition measurements is shown in Figure 1. Wood powder of 42-60 mesh was prepared from samples obtained near the positions 1, 3, 5 and 7. The lignin content was determined by the Klason method [8, 31]. Cellulose content was determined by the HNO_3-ethanol method. Holocellulose content was determined by the chlorite method and hemicellulose content was calculated as the difference between holocellulose content and cellulose content.

3. RESULTS AND DISCUSSION

3.1. Growth Stress distribution around the trunk

The GSI value was used in this study to estimate longitudinal growth stress on the surface of the standing trunk.

In poplar, growth stress is a good indicator of tension wood "severity", i.e. G-fibre proportion and G-layer thickness in species which can produce G-fibres [20, 21].

Figure 3 shows the GSI variation along the trunk periphery at breast height of the 6 trees. In all six trees, the upper-side values (position 1, Fig. 1) placed at 180° on the graph, were significantly higher than those of the lower sides (position 5, Fig. 1), corresponding here to 0° or 360°. Other GSI values were mostly distributed between those of the upper and lower sides. The change in upper-side GSI value among six trees did not show a significant trend with the lean angle. Except for the positions 180°, 135° and 225°, the GSI value varied very little, excluding the point 270° of tree PC2, which was abnormally high. The transverse section corresponding to each GSI measurement position was checked with microscopy; moreover, the visual assessment of the transverse sections of each position showed that all high GSI values were associated with
Figure 3. GSI variation along the trunk periphery at breast height. The upper sides correspond to 180°. Different lines indicate different trees.

a high proportion of G-fibres, except for that abnormal value where few G-fibres were observed. So in the further statistical analysis of this study, this value will be replaced by the mean value (170 μm) of the adjacent two values.

3.2. Growth stress/anatomical properties

Dadswell and Wardrop [19] have stated that in the fresh state, before any drying has occurred, tension wood fibres appeared to be in cross-section of exactly the same diameter as normal wood fibres. However, Chow [9] reported that tension wood fibres were narrower than those of normal wood in beech on isolated fibres. Similarly, Wardrop [55] and Jourez et al. [27] reported that in poplar (*Populus alba* and *Populus euramericana* cv. 'Ghoy', respectively), in the radial direction, the G-fibres were relatively narrower than the opposite wood fibres observed in cross-section. Onaka [42] and Scurfield and Wardrop [51] reported a larger tangential diameter of tension wood fibre in some species. In this study, a negative correlation ($r = -0.462$, significant at the 1% level) was found between cell diameter (no attention was paid to the radial or tangential directions) and GSI value (Fig. 4a). As high GSI values were observed on the upper sides of trunks, where a high proportion of tension wood is expected, and low ones on the lower sides containing opposite wood (Fig. 3), this result is more or less in accordance with some of the previous ones. The mean cell diameter and standard deviation was 19.8 ± 3.9 μm.

The average length of fibres and standard deviation around the periphery of the trunk at breast height in this study was 1347 ± 198 μm. There is no agreement in the literature regarding the length of tension wood fibres in comparison with that of normal fibres. Compared with normal fibres, tension wood fibres were reported sometimes as being longer [9, 27, 42], sometimes as being shorter (Giovanmi 1953, cited in Zimmermann [61]) and sometimes as having no marked difference [19, 51]. In this study a very significant positive correlation ($r = 0.751$, significant at the 1% level) was found between

fibre length and GSI values (Fig. 4b). It indicates that with the increase in growth stress, i.e. from normal wood to mild and severe tension wood, fibres become longer and longer.

The formation of tension wood is usually associated with the occurrence of eccentricity, with a wider ring at the upper side of the stem where tension wood is produced [2]. Eccentric radial growth either results from an increased duration of division or from a higher division rate in the cambium [54, 55]. As in normal wood formation, the fibre length is inversely related to the growth rate [22, 30, 33]. If eccentricity of tension wood arose from an increased division rate in the cambium, then the tension wood fibres would be expected to be shorter [54, 55]. Thus, for the case in this study, eccentricity of tension was suspected to be the result of increased duration of division. Furthermore, it has been evidenced that the duration of cambial activity is greater on the side of stems forming tension wood (Wardrop [54]; Priestley and Tong 1927, cited in Wardrop [55]).

In this study, the double cell wall thickness excluding the G-layer was measured for samples with different growth stress levels, and a significant negative correlation ($r = -0.812$, significant at the 1% level) was found between them (Fig. 4c). This means from normal wood to mild and severe tension wood the thickness of the cell wall excluding the G-layer decreased. This result was also confirmed in a recent study [20] which reported that with the increase in growth stress the other cell wall layers' (all cell wall layers excepting the G-layer) thickness decreased while the G-layer became thicker.

A very slight and not significant positive correlation existed in this study between GSI value and the diameter of cell lumen, after G-layer removal when present (Fig. 4d). As described above, the cell diameter decreased with an increase in GSI. Since, on the other hand, we showed [20] that the G-layer thickness increased with an increase in growth stress level, the real cell lumen diameter (G-layer not removed) should be negatively related to GSI. And when the G-layer is removed, the lumen should become bigger with the increase in growth stress level. The unapparent relationship found here could be partially explained by the decreased cell diameter related to the increased growth stress level.

Many researchers have reported the comparison of vessel proportion between tension and normal wood or between upper-side wood and lower-side wood, but not on vessel proportion variation during increased growth stress level. This study gave a very significant negative correlation ($r = -0.786$, significant at the 1% level) between vessel proportion and GSI value (Fig. 5a). In the previous studies, there was a general agreement that tension wood contained a lower vessel proportion than normal wood [9, 27, 42, 47, 55], except for Kaeiser and Boyce [29] and Kroll et al. [34], who reported opposite results. The decreased vessel proportion in tension wood could be partially explained by the auxin concentration. According to Aloni [3], the rate of vessel differentiation is determined by the amount of auxin obtained by the differentiating cell, while tension wood forms in the region with less IAA concentration [17, 38].

No apparent relationship was found between ray proportion and GSI (Fig. 5b). Onaka [42] and Jourez et al. [27]
Figure 4. Relationship between GSI (μm) and (a) cell diameter, (b) fibre length, (c) double wall thickness excluding the G-layer and (d) lumen diameter after G-layer removal. Error bars show 95% confidence intervals of mean.
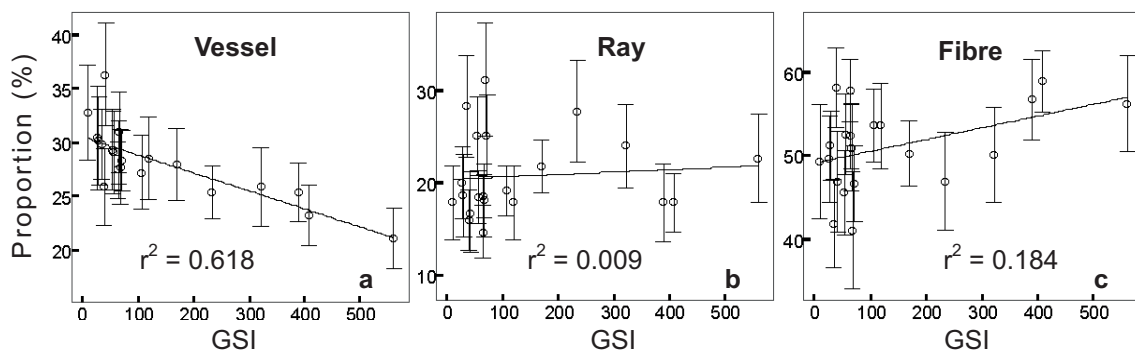

Figure 5. Relationships between GSI value (μm) and proportion (%) of wood tissues: (a) vessels; (b) parenchyma rays; (c) fibres.

also reported that ray proportion did not vary with wood type, normal or tension wood. A different result was reported by Chow [9], who observed that tension wood contained a larger proportion of rays, but was inconclusive.

Considering the results discussed above it is easy to reach the conclusion that fibre proportion increased with increased GSI value (r = 0.429, significant at the 5% level, Fig. 5c). This result is in accordance with Fang et al. [21]. Furthermore, they reported that with the increased growth stress level G-fibre proportion increased. Theses results can be used to explain the increased wood basic density; see below.

3.3. Growth stress/physico-mechanical properties

The average basic density and standard deviation of outmost samples at breast height of poplar I-19 (*Populus deltoides* Bartr. cv. "Lux" ex I-69/55) in this study were 0.39 ± 0.02 g/cm^3.

Chow [9], Lenz [36] Panshin and de Zeeuw [43], and Jourez et al. [28] compared tension wood and normal wood without

considering the severity of tension wood and reported a higher basic density of tension wood. Washusen et al. [57] stated a positive correlation between microdensity and tension wood fibre percentage. Similar results were also reported by Kroll et al. [34] and Clair et al. [12], while Arganbright et al. [4] and Lowell and Krahmer [37] did not observe a significant effect of lean or side on wood density. A lower density in tension wood was also reported in *Tilia* [43]. Basic density of samples located at different growth stress levels was compared in this study and a significant but weak positive correlation (Pearson r = 0.326, significant at the 5% level) between them was found (Fig. 6a). As with increased growth stress level decreased vessel proportion and increased fibre proportion were found (Fig. 5c), and furthermore increased G-fibre proportion and G-layer thickness [21], the increased basic density with increased growth stress level can be easily explained.

Mean and standard deviation of FSP were 30.3 ± 1.4%. A significant but weak negative correlation was found between FSP and GSI value (Fig. 6b). This could be explained by a difference in cell wall hygroscopicity between normal and tension wood. The hygroscopicity depends on the chemical
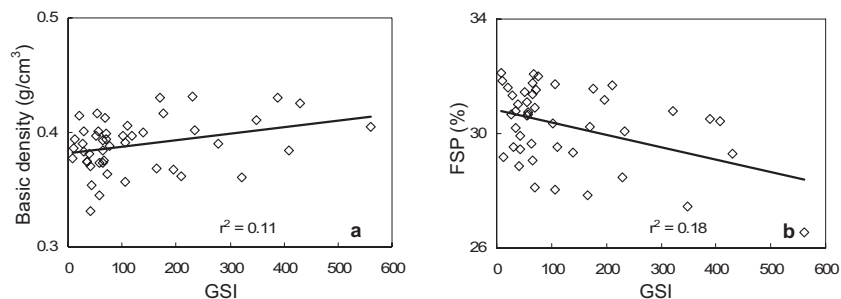

Figure 6. Relationships between GSI (μm) and (a) basic density (g/cm^3) and (b) FSP (%).
Figure 7. Relationships of (a) MOE (GPa) and (b) specific MOE (GPa·cm^3·g^{-1}) with GSI (μm).

Figure 8. Relationships of (a) compressive strength (MPa) and (b) specific compressive strength (MPa.cm^3.g^{-1}) with GSI (μm).

compositions of the cell wall, cellulose crystallinity, cell wall density and extractive contents. Among chemical components in cell walls, of the three major materials (lignin, hemicelluloses and cellulose) lignin has the lowest affinity for water and hemicelluloses the highest. The affinity of cellulose for water is between these two [10]. A lower hemicellulose content in tension wood was found in this study; see below, and also reported by Furuya et al. [26]. Furthermore, in the tension wood the G-layer has very high crystallinity [15, 39] which leads to low affinity for water.

A significant positive correlation (Pearson $r = 0.671$, significant at the 1% level) was found between MOE and GSI values (Fig. 7a). Similar results were reported by Coutand et al. [16]; that the Young's modulus of tension wood, green or dry, is higher than that of normal wood, with the three points bending test method. However, some other authors did not find any relation with growth stress level or with G-fibre percentage [9, 50]. Increased MOE with increased GSI value could be explained to some extent by the increased density (Fig. 6) [16],

but it still increased with the increase in GSI value even after normalising for density (i.e. specific MOE) (Fig. 7b). This could be explained by the difference in microfibrillar angle between S$_2$ and G-layers, as has been observed and modelled for softwoods [32, 49], but also by differences in chemical composition or other structural features. A comprehensive model relating the macroscopic behaviour in the L direction to the parameters of cell wall composition (e.g., [60]) would be required to analyse these relationships more deeply.

With the increase in GSI value, a decreased compressive strength was found here (Pearson $r = -0.466$, significant at the 1% level) (Fig. 8a). A similar relation was reported by Ruelle [46] on three tropical species. The lower compressive strength in tension wood could be explained by the lower lignin content (see below), and longer and thinner fibre (see above), as suggested by Frey-Wyssling (1936, cited in Wardrop and Dadswell [56]) that when a compressive stress is applied to a fibre the micelles tend to buckle because of their great length as compared with their lateral dimensions.
Figure 9. Relationships between GSI (μm) and shrinkage (%) of (a) L, (b) T and (c) R.
Figure 10. Relationships between GSI value (μm) and chemical compositions: (a) cellulose content (%), (b) lignin content (%) and (c) hemicellulose content (%).

Thus, in an unlignified fibre similar to that of tension wood, buckling could occur easily, giving rise to the formation of slip planes and minute compression failures. However, in a lignified fibre, lignin, packed between the micelles, resists the tendency of the micelles to buckle. This could explain the common occurrence of slip planes and minute compression failures in the cell walls of tension wood observed by Wardrop and Dadswell [18, 19, 56].

Specific compressive strength was also presented (Fig. 8b). It is easy to understand the negative correlation with GSI value because of the decreased compressive strength and increased density. A similar result was reported by Onaka [42].

There is no bifurcation on the higher L shrinkage of tension wood than that of normal wood [12, 19, 28, 56, 60]. This was further confirmed in this study by the significant positive correlation between L shrinkage and GSI value (Fig. 9a). High longitudinal shrinkage in tension wood can be explained by the evidence of the longitudinal shrinkage in the G-layer itself [13]. However, the L shrinkage of the G-layer remains paradoxical and its mechanism is still unknown.

Few studies have been done on the transverse shrinkage of tension wood and the results are contradictory. Washusen and Ilic [58], and Clair et al. [12] reported a higher transverse shrinkage in tension wood, while Barefoot [5], Arganbright et al. [4], and Fang et al. [20] observed a lower one. In this study T and R shrinkages were found strongly and weakly, respectively, correlated negatively with GSI value, and both correlations were significant (Fig. 9b, 9c). This result was completely accordant with that observed on 20-μm-thick sections of poplar in our previous study where T and R shrinkages at both mesoscopic (section) and microscopic levels were dis-

cussed, and an explanation for the lower transverse shrinkage of tension wood was given [20]. That explanation could be used here even though massive wood, not section, was studied.

3.4. Chemical composition

A positive correlation of cellulose content and negative ones of lignin and hemicellulose contents with GSI value were found in this study (Fig. 10). It should be mentioned, however, the samples for chemical composition measurements were collected at relatively big areas near GSI measurement positions (Fig. 1). Furthermore, on the low scale of GSI values all three contents varied a lot (Fig. 10). Therefore, the obtained correlation should be considered with some caution.

The distribution of cellulose, lignin and hemicellulose contents around the trunk of different trees is presented in Figure 11. The cellulose content (Fig. 11a) rose to a maximum in the upper sides of all six trees where the highest GSI values were measured (Fig. 3) and the paired (by different trees) samples t-test showed it was significantly higher in the upper side than in the other sides, but no significant difference existed between lower and lateral sides (Tab. II). A contrary result was found for the lignin content (Fig. 11b). Four out of six trees showed the lowest hemicellulose content (Fig. 11c) located in the upper sides, but the differences among different sides were not significant after the paired samples t-test.

Tension wood is generally described as containing a high proportion of cellulose and being less lignified than normal wood [26, 45, 53]. Our results showed that the studied species of poplar in general has similar chemical properties. Similar

Table II. Paired (by different trees) samples *t*-test of chemical composition differences among upper, lower and lateral sides. Lateral side value is the mean of positions 3 and 7 (Fig. 1). NS = not significant, * significant at the 0.05 level, ** significant at the 1% level.

	Upper-lower	Upper-lateral	Lateral-lower
Cellulose (%)	*	**	NS
Lignin (%)	*	*	NS
Hemicellulose (%)	NS	NS	NS

results were also reported by previous studies on different species [9, 41, 52, 56].

4. CONCLUSION

In this study a quantitative assessment of growth stress level was used to characterise the wood on 6 inclined poplar I-69 (*Populus deltoids* cv. I-69/55) trees at breast height. The following conclusions are drawn:

– The highest GSI values were located in the upper sides of the inclined trunks. Other GSI values were mostly distributed between those of upper and lower sides.
– Negative correlation was found between cell diameter and GSI value. With the increase in growth stress, i.e. from normal wood to mild and severe tension wood, fibres become longer and longer and the thickness of the cell wall excluding the G-layer decreased. A very significant negative correlation was found between vessel proportion and GSI value. No apparent relationship was found between ray proportion and GSI. Fibre proportion increased with increased GSI value.
– GSI was significantly but weakly correlated positively with basic density and negatively with FSP. With the increase in GSI value, MOE increased, compressive strength decreased, L shrinkage increased, and T and R shrinkage decreased.
– The cellulose content rose to a maximum in the upper sides where the highest GSI values were measured. A contrary result was found for the lignin content. Four out of six trees showed the lowest hemicellulose content located in the upper sides, but the differences among different sides were not significant.
