Abstract – Fairly strong positive relationships between stiffness and density have often been reported. No stronger relationships have been found when using parameters of density profiles based on an earlywood–latewood boundary. In this study, we attempt to model the relationships among the stiffness of different samples and simple parameters derived from microdensity profiles, not established according to an earlywood–latewood boundary. Furthermore, we try to determine if there is a genetic variation for the relationship between stiffness and density. From the results, we find that the strongest relationship between a single density parameter and stiffness is $r^2 = 0.78$, whereas it is $r^2 = 0.37$ when involving a *classical* within-ring density parameter. At clone level, r^2 ranges from 0.88 to 0.95, while it is 0.51 for the bulked samples. The mathematical form of the models differ from one clone to another: there is a genetic effect on the models. This could mean that different clones different build their stiffness in different ways. (© Inra/Elsevier, Paris.)

Résumé – Modélisation du module d'élasticité à l'aide de données microdensitométriques : méthodes et effets génétiques. 2^e partie. On a souvent mis en évidence d'assez fortes relations entre la rigidité et la densité du bois. Ces relations n'étaient pas plus fortes quand on a essayé d'expliquer la rigidité à l'aide de paramètres microdensitométriques intra-cerne basés sur une limite bois initial-bois final. Dans cette étude, nous tentons de modéliser la rigidité d'un échantillon de bois à l'aide de paramètres simples calculés à partir de profils microdensitométriques, mais non basés sur la limite classique bois initial-bois final. De plus, nous cherchons si les modèles décrivant cette relation sont différents d'une unité génétique à l'autre. Les résultats montrent que les modèles bâtis à l'aide de nos nouveaux paramètres sont plus précis que ceux construits à l'aide des paramètres intra-cernes classiques (par exemple, pour les mêmes échantillons, r^2 passe de 0,37 à 0,78 quand la rigidité est expliquée à l'aide d'un de ces nouveaux paramètres, plutôt qu'à l'aide de la densité du bois final). Au niveau clonal, le r^2 varie de 0,88 à 0,94, alors que tous échantillons confondus, il est seulement de 0,51. De plus, la forme mathématique des modèles est différente d'un clone à l'autre. Donc il existe un effet génétique sur la relation rigidité-densité. Si ces résultats sont confirmés, cela signifie que différents clones ont différentes manières de construire leur rigidité. 1. INTRODUCTION

Since the end of the nineteenth century, density has been acknowledged as the best single predictor of wood mechanical properties [1, 15, 20–22, 33]. Modulus of elasticity (MOE), or stiffness, is a basic mechanical property for softwoods, especially when they are used as solid wood products in structure [8, 20]. The first part of this report presents a non-destructive tree-bending machine, the *modulomètre*, which is similar to the device elaborated by Koizumi and Ueda [13] and used to measure the stiffness of standing tree trunks (trunk MOE).

Fairly strong positive relationships between MOE and specific gravity of samples of different shapes and sizes have often been reported: e.g. on standard wood samples of *Pseudotsuga menziesii* (coefficient of determination $r^2 = 0.64$ [15]), *Pinus yunnanensis* ($r^2 = 0.73$ [30]), *Picea koraiensis* ($r^2 = 0.50$ [30]), *Larix decidua* ($r^2 = 0.52$ [23]), on small uniform within-ring wood samples of *Picea abies* ($r^2 = 0.83$ [4]) and on mini-bending samples of *Pseudotsuga menziesii* ($r^2 = 0.67$ [25]). On *Picea abies* standard wood sample, de Reboul [9] found that r^2 could reach 0.76.

As wood properties and wood anatomy are intimately related [7, 11, 24, 32], some researchers tried to correlate the MOE and some within-ring density parameters computed from density profiles (like X-ray density profiles [24]). They did not find more satisfying relationships than those between the MOE and the sample specific gravity: e.g. Gentner [12], reporting on *Picea sitchensis*, found $r^2 = 0.45$, and Choi [6], reporting on *Pseudotsuga menziesii*, found $r^2 = 0.54$, both with latewood density. Takata and Hirakawa [28], on *Larix kaempferi*, found $r^2 = 0.55$ with a mean ring density and $r^2 = 0.54$ with latewood percentage. On *Pseudotsuga menziesii*, in Part I of this report, the authors found $r^2 = 0.37$ with latewood width. McKimmy [18], on *Pseudotsuga menziesii*, found that earlywood density was more related to strength properties than latewood density: MOE is dependent on the stiffest wood in the ring (i.e. latewood), while strength is dependent on the weakest wood in the ring, where fracture starts (i.e. earlywood).

All used within-ring density parameters based on an earlywood–latewood boundary. It is clear that, with regard with the MOE–density relationship, these parameters are not more relevant than the mean density (or the specific gravity) of the sample. On the other hand, complete density profile contains a huge amount of data (within-ring local density variability) which are ignored when summing up a whole ring or a whole profile with mean density. Thus, we question whether the early-

wood–latewood model is the best way to sum up the information enclosed in a density profile.

The aim of this study is to attempt to better explain the MOE variations using the data contained in a density profile. A first step toward this was complied by Mamdy et al. ([17] and Part I of this report). They found a highly significant relationship among trunk (and board) MOE and parameters of polynomials describing the density variations of a given ring density segment. This segment was mainly located in the latewood. Values of r^2 ranged from 0.58, $P < 0.001$ to 0.80, $P < 0.001$, according to the number of polynomial coefficients involved in the relationship. However, the polynomial coefficients have no evident biological and physical meaning. Therefore, in this report, we try to model the relationships among trunk, board and standard samples MOE and some simple parameters derived from microdensity profiles with a simple biological meaning, not established on the earlywood–latewood limit.

Another explanation for the lack of accuracy of the models describing the MOE–density relationship is that the mathematical shape and/or the parameters of the models used to outline this relationship may be different from one genetic unit to another. Various authors noted that the growth rate–wood density relationship on *Picea abies* [5, 26] and *Picea mariana* [31] was significantly different from one genetic unit to another. Hence, and for standard sample MOE only, we will try to answer the question “Is there genetic control for the relationship between MOE and density parameters?” If yes, this genetic variation could be used by the tree breeder to select genetic units with more favourable relationships.

2. MATERIALS AND METHODS

Plant material and study data are described in Part I of this report. *Figure 1* illustrates the samples and the measurements. For the trunk MOE study only, two types of profiles were used: the microdensity profile, i.e. the evolution from pith to bark of the local density, and the evolution from pith to bark of ‘density $\times 2\pi$ radius’ (weighted density profile), which gives an estimation of the biomass produced by the cambium during each growth period (*figure 2*).

Results from numerous authors [6, 12, 16, 28] suggest that, in the frame of the earlywood–latewood modelling of the ring density profile, the most relevant part of the ring is the latewood. *Figure 3* shows two density profiles, one from a stiff sample, and the other from a flexible one. It is clear on this example that there is more ‘high density wood’ (latewood) in the stiff than in the flexible sample. It is evident both on heuristic reasoning

Figure 1. Presentation of the samples and measurements.

Figure 2. Upper panel: a raw density profile. Lower panel: a weighted density profile. The weight is proportional to the volume of the wood sheath correspondent to the local density profile value. We assume that the stem shape is cylindrical.

and on this example that MOE might be related to the amount of latewood within a sample. However, as the earlywood–latewood boundary is a physiological limit, based on Mork’s principle [19] that helps to locate in the ring the point where the cambium activity changes abruptly during the growing season, there is no a priori reason why MOE should be related to that boundary. The MOE–density relationship is, in this example, a mechanical relationship. Therefore, we based our study

Figure 3. Upper panel: density profile of a stiff tree. Lower panel: density profile of a flexible tree. It is clear that the amount of ‘high density wood’ is larger in the stiff than in the flexible profile.

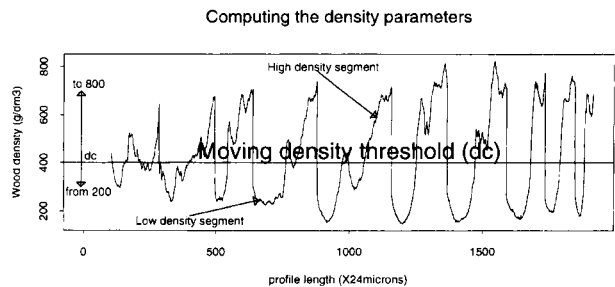

Figure 4. The study density parameters were computed according to a moving density criterion (dc) threshold. This threshold divides the complete density profile into two ‘high density’ and ‘low density’ segments.

on an exhaustive search of the location of high density wood.

First, using a moving density criterion (dc), the complete profiles were divided into two parts: *high density* and *low density* segments, according to the local density compared to dc (figure 4). The dc parameter ranged from 200 to 800 $g\cdot cm^{-3}$ (step 10 $g\cdot cm^{-3}$). Then, for each dc value, the following parameters were computed: mean densities and length of both high and low density segments (respectively, D_{hi} , D_{lo} , L_{hi} and L_{lo} , which may be seen as a prolongation of the earlywood–latewood densities and width), cumulated density for the high density segment (D_{cu}), energy (E_{ne}) and number of crossing points between the dc line and the profile (N_b).

Figure 5. The five density parameters of the study are shown in this figure. On the top profile, Dhi is the mean density of the high density segment, and Dlo is the mean density of the low density segment. On the middle profile, Llo is the length of the low density segment, and Nb is the number of intersections between the density profile and the moving density criterion (dc) threshold. On the bottom profile, the energy (Ene) is the surface between the squared profile and the squared dc threshold.

Figure 5 illustrates these parameters. Dcu is the surface between the dc threshold and the high density segment of the profile. The energy (Ene) of a density profile x_i is $\sum_{i=1}^n x_i^2$, and is a parameter commonly used in signal treatment (Trubuil, personal communication). For density values of dc over 500–600 g·dm⁻³, Nb is twice the number of high density peaks in the profile (latewood peaks and false rings).

To investigate the possible redundancy of the density parameters, a correlation study was conducted among them. For boards and standard samples density profiles, three parameters are very strongly related ($r^2 > 0.99$, $P < 0.001$, whatever the study level): Lhi, Dcu and Ene. Thus two of them, Lhi and Dcu, were excluded from the study of the modelling of the boards and of the standard

Table I. Samples and corresponding variables.

Sample	Variable
Trunk, board, standard sample	MOE
Density profile	Dhi, Dlo, Llo, Nb, Ene

samples MOE (but not from the trunk MOE study, where the used profiles were the biomass profiles). Table I shows the samples and the corresponding variables.

A correlation study (using Pearson's linear correlation coefficient) and a multiple linear regression study (using the stepwise *efroymsen* method [27]) were then conducted among all the density parameters and the MOE at all sample and genetic units levels.

2.1. Relationships between MOE and density parameters at different levels (sample type)

For each density parameter and each type of sample the optimum dc level was noted: this optimum level is the dc value for which the r^2 of the single relationship between the density parameter and the MOE is maximum. *Figure 6* shows an example of the evolution of the r^2 of the relationship between the MOE and one parameter, Ene, when dc varies from 200 to 800 g·dm⁻³.

2.2. Genetic control of the MOE-density relationship

For the standard samples, for each clone, simple and multiple linear regression studies were conducted clone by clone. For the multiple relationship, the number of explanatory variables was reduced from five to a maximum of two. Then a second multiple linear regression was conducted, imposing the same mathematical model (fixing the same two parameters for all the clones).

Figure 6. The selection of the optimal moving density criterion (dc) value for a given density parameter (here, energy [Ene]). The line shows the evolution of the strength of the relationship between the modulus of elasticity (MOE) and the parameter when the dc threshold varies from 200 to 800 g·dm⁻³. The optimal dc value coincides with the maximum r^2 .

3. RESULTS

3.1. The trunk MOE and density parameters relationships

The correlation coefficients are maximum for the parameters calculated from the *weighted* density profiles recorded on the samples collected at 2 m high in the stems. Quite high single relationships were found between MOE and, respectively, Nb ($r^2 = 0.58$, $P < 0.001$) and Lhi ($r^2 = 0.49$, $P < 0.001$). *Table II* gives the complete results for the single relationships.

3.2. The board MOE and density parameters relationships

The correlation coefficients are maximum for the parameters calculated from the density profiles recorded on the samples collected at 1.3 m high in the stems. High single relationships were found between MOE and, respectively, Ene ($r^2 = 0.78$, $P < 0.001$), Nb ($r^2 = 0.71$, $P < 0.001$) and Dhi ($r^2 = 0.66$, $P < 0.001$) (*table III*).

Table II. The best single relationships between the trunk modulus of elasticity and the density parameter.

Density parameters	dc (g·dm ⁻³)	r^2	P
Dhi	300	0.18	0.0943
Dlo	740	0.15	0.0961
Lhi	620	0.49	0.0006
Llo	420	0.28	0.0165
Dcu	600	0.28	0.0161
Ene	800	0.24	0.0284
Nb	660	0.58	0.0284

Table III. The best single relationships between the board modulus of elasticity (MOE) and the density parameters, according to the moving density criterion (dc).

Density parameters	dc (g·dm ⁻³)	r^2	P

Dlo	780	0.64	< 0.001
Llo	400	0.32	0.0094
Ene	450	0.78	< 0.001
Nb	710	0.71	< 0.001

3.3. The standard sample MOE and density parameters relationships

We studied the quality of a linear regression among, on the one hand, the MOE, and on the other hand, the parameters of the previous section. This was done successively on the 80 samples, 40 top samples and clone by clone (eight top samples per clone).

We found that for all 80 samples, whatever the density level, the strength of the relationship is low. The maximum values were found for Dlo ($r^2 = 0.22$, $P < 0.001$) and Dhi ($r^2 = 0.17$, $P < 0.001$) (table IV).

For the 40 top samples, r^2 strongly increased. The maximum values, still moderated, were found for Dhi ($r^2 = 0.48$, $P < 0.001$), Dlo ($r^2 = 0.$, $P < 0.001$) Llo ($r^2 = 0.37$, $P < 0.001$), Llo ($r^2 = 0.40$, $P < 0.001$) (table V).

3.4. Genetic effects on the standard samples MOE and density parameters relationships

Clone by clone, the relationships between MOE and the density parameters were always stronger when the samples were only those from the upper part of the stem.

Table IV. The best single relationships between the 80 standard sample modulus of elasticity (MOE) and their density parameters.

Density parameters	dc (g·dm ⁻³)	r^2	P
Dhi	360	0.17	0.0002
Dlo	420	0.22	< 0.001
Llo	670	0.08	0.0096
Ene	660	0.09	0.0085
Nb	690	0.15	0.0004

Table V. The best single relationships between the 40 top standard sample modulus of elasticity (MOE) and their density parameters.

Density parameters	dc (g·dm ⁻³)	r^2	P

3.5. Best models (multiple linear relationships) relating MOE and wood density parameters

Tables XI and XII show the parameters involved (**X**) in the best multiple linear relationships (according to the stepwise *efroymsen* method [27] and the associated adjusted multiple r², respectively, for the trunk MOE (table XI) and the boards and standard samples MOE (table XII). The coefficient of determination is maximum for upper stem samples and within-clone models.

Table XIII presents the best multiple linear models for the five clones, without any condition fixed for the choice of the parameters. Parameters involved in the models are very different from clone to clone. With our study parameters, it seems difficult to select one model mathematical form suitable to all the clones.

Table XIV gives the results of an attempt to select only one mathematical form common to all five clones. It contains the best multiple linear models for these five clones, with the mathematical shape of the model fixed as follows: $MOE = a + b \cdot Dlo + c \cdot Nb$. Estimated values of the model parameters are very different from one clone to the other. Clone 1453 in particular is very different from the four other clones from that point of view. The r² square value of that clone model (0.56) is relatively low, compared to that in table XII (0.95).

4. DISCUSSION AND CONCLUSION

It is possible to calculate simple biological parameters strongly or very strongly related to trunk, board or standard sample MOE. These relationships are stronger than those among MOE and within-ring classical parameters based on the earlywood–latewood model (for trunk and

Table XIII. The best multiple linear models for the five clones, without any condition fixed for the choice of the parameters.

Clone 1483	MOE = -13179 + 56.Dlo
Clone 1464	MOE = 11855 - 15.Dlo + 391.Nb
Clone 1439	MOE = 15169 - 22.Dlo + 772.Nb
Clone 1489	MOE = 43275 - 51.Llo + 444.Nb
Clone 1453	MOE = 12034 - 1712.10 ⁴ .Ene + 620.Nb

1489	9662	-20.3	892.7	0.76
1453	-5946	56.3	496.7	0.56

board respectively, 0.42, $P < 0.01$ and 0.37, $P < 0.01$ in [16], 0.58, $P < 0.001$ and 0.78, $P < 0.001$ in this study; tables II and III).

The high relationship between Ene (sum of the squared densities) and board MOE suggests that the relationship between local MOE and density is non-linear such as that noted by Chantre [4] on Norway spruce. This could mean that the increase in density in the late-wood is not only related with a decrease of the porosity, but also with an increase of the cell wall MOE, itself linked with a smaller microfibril angle (Fournier-Djimbi, personal communication).

In a bending test, if strength direction is perpendicular to the ring limits, the outer layers play a greater role than inner layers [2, 10]. That is certainly why the trunk MOE–density relationship is stronger for parameters from biomass profiles (radius² weighted) than for parameters from density profiles. Weighing density with radius³ was also tried (thus assuming that the outer layers' influence was not linked to their mass, but rather to their rotation inertia); however, this did not improve the relationships.

For the standard samples, the general relationship between MOE and density parameters is far stronger (r^2 from 0.22 to 0.48; tables IV and V) when excluding the bottom standard samples. Thus, the MOE of a 36 cm long standard sample taken just over the stump cannot be accurately explained by density parameters of the same

sample. Systematic higher compression wood content in the stem part under 1 m from the ground could lead to an interpretation. Timell [29], however, stated that results are contradictory when researchers try to answer the question of whether compression wood occurs more frequently in the lower part of the stem. Zobel and colleagues [32, 33] wrote that in a zone approximately 0.5 to 1 m from the ground line, wood is very erratic and non-uniform, and not representative of the tree. Larson [14] noted that cells in stump wood show distortion in radial alignment, with regard with cells in stem wood, and that wavy grain and whirled grain occur more frequently in or near the stump than higher in the stem. Hence, we can conclude that variation within a sample taken near the stump is larger than that of the same sample taken near or over breast height. Such a sample density structure will not be accurately estimated from that of a thin wood specimen taken at one of its ends. It is therefore clear that the sample location within the tree is important and has to be known.

Combining the best parameters in multiple linear relationships is a technique to explain from 25 to 95 % of the natural variability for MOE. For standard samples, one parameter seems to be more interesting than the others – Nb, found respectively in seven of nine multiple relationships. This parameter is twice the number of high density peaks in the density profile segment. It is therefore related to both the number of false rings, and the number of rings (itself very closely related with the ring width) in the samples. However, most parameters involved in the relationships are different for trunks, boards, standard samples and standard samples at clone level (not the same number of parameters, not the same parameters, not the same dc density threshold for the same parameters, except maybe for Nb, for which the dc value is nearly always between 660 and 740 g·dm⁻³). The clonal models are always far more precise than the general model, and the best multiple linear relationship differs from one clone to another. Trying to fix a given mathematical shape for the multiple linear model decreases the precision of two or three of five clonal models. No attempt has been made to determine if this precision decrease was significant.

The clone 1453 model is completely different from the other four. The MOE of this clone is negatively (and significantly, $P < 0.05$) related to Dhi and Ene, while the same relationships are positive at all others levels.

Hence, the microdensity profile can explain most of the MOE variation. The density profiles used in the models at stem and board levels are the same. They come from samples sawn in the boards. Therefore, they are likely to better describe density variations in the board than in the complete stem. That is certainly why the

MOE–density–parameters relationship is stronger for the boards than for the stem.

Genetic variation for the relationships between wood properties and growth traits have recently been found at different genetic levels (e.g. [4, 26, 31]). In this study, clonal models are far more precise than general models, and are different from one clone to another: for this reason we assert that there is a strong genetic effect on the relationship between density and MOE. It means that genetic units could build their stiffness in different ways.

Taking this genetic effect into account could be a way to increase the accuracy of models relating mechanical properties and density.

Breeders may use the differences among the models as secondary traits for selection and some ways to build wood stiffness could be better than others.

This study proves that simple wood density parameters can explain, for the most part, the natural variation for MOE. Nevertheless, these parameters may not be the most relevant ones to describe the genetic effect on the study relationships. They are closely related to each other. Using parameters derived from models calculated using advanced techniques such as wavelet modelization, and/or other parameters than density parameters (grain angle, Nepveu, personal communication, microfibril angle, [3]) may be a more *efficient* and *objective* way to determine what will, in a density profile, explain the stiffness of a piece of wood.

Another way to increase modelling efficiency could be to imagine and test physical models based on hypotheses about the relationships between local MOE and local wood density, and then compare them to the statistical models of our study.

These results were obtained on only five clones and 20 trees. Although conclusions were drawn using only statistically highly significant parameters, new studies using more clones and more trees per clone would be greatly beneficial.

Acknowledgements: We wish to warmly thank Frédéric Millier, Daniel Lacan, Dominique Veisse and Patrick Poursat, Inra research technicians, for their very valuable help and comments all along this study.
